(Dated: March 25, 2014)

The nucleation of reversed magnetic domains in Pt/Co/AlO_x microstructures with perpendicular anisotropy was studied experimentally in the presence of an in-plane magnetic field. For large enough in-plane field, nucleation was observed preferentially at an edge of the sample normal to this field. The position at which nucleation takes place was observed to depend in a chiral way on the initial magnetization and applied field directions. An explanation of these results is proposed, based on the existence of a sizable Dzyaloshinskii-Moriya interaction in this sample. Another consequence of this interaction is that the energy of domain walls can become negative for in-plane fields smaller than the effective anisotropy field.

PACS numbers: 75.70.Ak, 75.60.Jk

Current-induced domain wall motion in magnetic nanostrips with perpendicular magnetic anisotropy (PMA) is the subject of intense studies. Driving a train of very narrow ($\simeq 10$ nm) domain walls (DW) in the same direction and at high velocity has important potential applications in all-magnetic memories [1] or logic circuits. The large DW velocities and their motion against the electron flow found for non-centrosymmetric stacks, in which a magnetic layer is in contact with a heavy metal on one side only, cannot be explained in terms of the spin-transfer torque (STT) [2] alone. Several torques deriving from spin-orbit interactions at the interfaces or in the bulk of the heavy metallic layers have to be taken into account. Two main mechanisms giving rise to spin-orbit torques (SOT) have been identified, the Rashba effect [3–5] and the Spin Hall effect (SHE) [4, 6, 7].

Recently, it was shown that the large velocities of current-driven domain walls and their direction of motion in Pt/Co/AlO_x could be understood if domain walls were assumed to have Néel internal structure and a fixed chirality [8]. Such domain walls, called Dzyaloshinskii domain walls (DDW), are stabilized by the presence of a non-compensated interfacial Dzyaloshinskii-Moriya interaction (DMI) [9, 10]. This interaction, which derives from the combination of low structural symmetry and strong spin-orbit coupling, favours helicoidal magnetic structures and skyrmion lattices if the interaction is strong [11–14] or DW with a fixed structure and chirality for a weaker interaction [8, 13, 15]. The anti-damping SOT associated to the absorption, at the Pt/Co interface, of the spin current generated by SHE in the Pt layer can then explain the large velocities of DDW.

The presence or not of DMI in ultrathin films with PMA is still under debate, calling for additional experiments. Very high resolution magnetic microscopy is the

privileged technique to directly investigate the internal structure of such narrow domain walls. Recent experiments using spin-polarized LEEM have indeed shown that, in Pt/(Co/Ni)_n multilayers, domain walls are of the Néel type [15]. The presence of chiral Néel DW may be also highlighted by less demanding experiments in which field and current-driven DW dynamics are studied in the presence of an in-plane magnetic field, applied normal to the DW. In several non-centrosymmetric stacks, $\downarrow\uparrow$ domain walls (separating up and down domains) and $\uparrow\downarrow$ DW have been found to move at different speeds, depending on the strength and the direction of the in-plane field. The symmetry of this effect has been considered as a proof that DW have Néel internal structure and a fixed chirality [16–19]. Field-driven measurements [19] can address more directly the effect of an in-plane field on the internal DW structure and therefore on DW dynamics, because of the absence of the effective fields induced by STT and SOT in the case of current-driven dynamics.

In this Letter we show for Pt/Co/AlO_x microstructures a new kind of chiral effect: in the presence of an in-plane magnetic field, nucleation of reversed domains takes place preferentially at one edge of the sample, oriented perpendicular to this field. The side at which nucleation takes place depends on the direction of both in-plane field and initial magnetization. The asymmetry is thus chiral, and we show that DMI can explain this.

The experiments were carried out on Pt(3 nm)/Co(0.6 nm)/AlO_x(2 nm) layers patterned by electron beam lithography into two large injection pads connected by micrometric strips. The strips were used for field and current-driven domain wall dynamics (not shown here) while the nucleation experiments were carried out on the pads. The films were deposited on a Si/SiO₂ substrate by magnetron sputtering. Samples

were oxidized *in situ* by oxygen plasma in order to induce PMA. Magnetization reversal was studied using magneto-optical Kerr microscopy. In each experiment, magnetization is first saturated with an out-of-plane magnetic field (H_z). Nucleation of reversed domains is then induced by an opposite H_z field pulse, under a DC in-plane field H_x . Several samples with similar composition and varying magnetic anisotropy have been measured.

Figure 1 illustrates an example of the occurrence of chiral nucleation and the symmetry of this effect. When an H_z field pulse (amplitude 18 – 20 mT and length 50 – 100 ms) is applied antiparallel to the initial magnetization direction, magnetization reversal is initiated by the nucleation of a reversed domain at a particular spot of the sample, away from the edges, corresponding to a local defect (Fig. 1(a)). When a sufficiently strong in-plane field H_x is applied at the same time as H_z , new nucleation centers appear at one edge of the pad. Starting from positive (\uparrow) saturation (corresponding to dark contrast in the Kerr images), a positive H_x field (along the positive x axis) promotes nucleation of reversed \downarrow domains at the left side of the sample (Fig. 1(c-e)). As the amplitude of H_x increases, the nucleation probability increases but no nucleation appears at the right edge of the sample, up to $\mu_0 H_x = 260$ mT. If either the initial magnetization direction or the H_x field direction is reversed, the nucleation takes place at the opposite side. Figures 1(e-f) show indeed that nucleation takes place at the right side when a negative H_x field is applied starting from the same \uparrow saturation. Similarly, nucleation takes place on the right side when H_x is kept positive but the initial magnetization is reversed (\downarrow) (Fig. 1(g-h)). This shows that the observed asymmetry is in fact chiral.

The nucleation field $H_{z,n}$ was measured as a function of H_x for a sample having an anisotropy field of 700 mT (slightly weaker than that of the sample shown in Fig. 1) both for a defect within the film and at the sample edges. The length of the H_z pulse was fixed at 20 ms. For a defect within the film, $H_{z,n}$ was defined as the field for which the domain appears with 100% probability. For the edges, $H_{z,n}$ was defined as the field for which 10-15 domains systematically nucleate [20]. The main result of these measurements, shown in Fig. 2, is that while the nucleation field of a domain within the film is almost H_x -field independent, $H_{z,n}$ strongly decreases with the in-plane field for the domains nucleating at the sample edges.

The chiral behavior of magnetization reversal cannot be explained by simply invoking a local reduction of anisotropy along the sample edges, which would keep the symmetry between opposite edges. In order to explain the observed chiral nucleation, a phenomenon which breaks the symmetry of the system when an H_x field is applied has to be invoked. A possible origin of this phenomenon is the presence in non-centrosymmetric

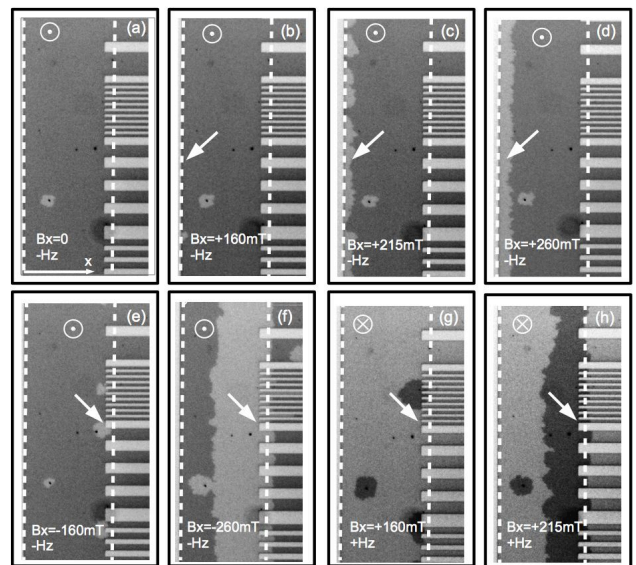

FIG. 1. Kerr images showing the chiral nucleation of domains at one side of the pad of the Pt/Co/AlO_x microstructure, by application of an out-of-plane field pulse. (a)-(d): magnetization is initially saturated \uparrow and $B_x = 0, +160, +215$ and $+260$ mT; (e-f) magnetization is initially saturated \uparrow and $B_x = -160$ mT and -260 mT; (g)-(h) magnetization is initially saturated \downarrow and B_x is $+160$ mT and $+260$ mT. The width of the pad is 70 μm . The dotted lines highlight the left and right edges of the pad and the arrows show the side of the sample where nucleation takes place.

FIG. 2. (color online). Nucleation fields measured as a function of in-plane field H_x for the reversed domain in the middle (squares) and at the left edge of the sample (circles). Note the difference of scales between the two axes.

Pt/Co/AlO_x stacks of a non-vanishing DM interaction which stabilizes Néel walls. We thus quantitatively investigate this hypothesis using two models.

Zero temperature model. In real samples (i.e. including defects), magnetization reversal is controlled by few defects acting as nucleation centers [21]. Chiral nucleation

requires defects with a chiral micromagnetic structure around them. DMI provides such a state at sample edges, inducing locally a tilt of the magnetization [22]. When an in-plane field normal to an edge is applied, the tilt angle depends on its orientation (parallel or anti-parallel to the field) and favored nucleation at one edge can be expected. Using the same 1D model in the x direction normal to the edge as in [22], the edge tilt angle θ is given by

$$m_x = \sin \theta = \pm \Delta \frac{D}{2A} + \frac{H_x}{H_{K0}}, \quad (1)$$

where D is the DMI constant, A the exchange constant, $H_{K0} = 2K_0/(\mu_0 M_s)$ the anisotropy field (K_0 is the effective anisotropy constant), $\Delta = \sqrt{A/K_0}$ the nominal domain wall width and the \pm sign refers to the two edges of the sample along x . Figure 3(a) sketches the effect of H_x and H_z on the micromagnetic configurations.

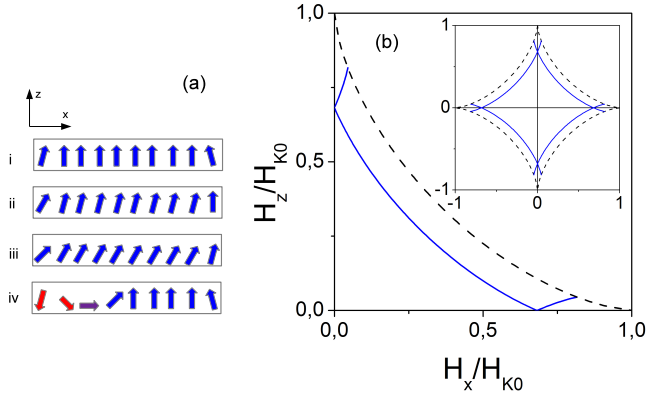

FIG. 3. (color online). a) Sketch of the micromagnetic configuration within a microstructure with DMI in zero applied field (i), under an x field (ii), under an additional negative z field (iii), and after reversal, with a domain wall of magnetization parallel to the x field (iv). b) results of a 1D calculation showing the reversal field for $D/D_{c0} = 0$ (dashes) and 0.5 (lines). For $D \neq 0$ an easy and a hard branch develop, corresponding to the reversal at the two edges of the microstructure. Inset: complete astroids.

In the absence of thermal fluctuations, the solution for the onset of magnetization instability at the edge can be mapped [20] to a solution of the Stoner-Wohlfarth model [1]. Figure 3(b) shows the reversal field H_z versus H_x (normalized to H_{K0}), calculated for different D/D_{c0} (with $D_{c0} = 4\sqrt{AK_0}/\pi \equiv \sigma_{00}/\pi$ giving the onset of the spontaneous formation of magnetization cycloids). For $D = 0$, the standard Stoner-Wohlfarth astroid is obtained and no difference occurs between the sample edge and the center. For a finite D , the edge reversal field with $H_x = 0$ decreases by a factor $[1 - (2/\pi)D/D_{c0}]$. As H_x is applied, the astroid splits into two branches revealing the difference between the two sample sides: on the side where m_x is initially parallel (resp. anti-parallel) to

H_x the tilt is larger (resp. smaller) and the reversal field decreases (resp. increases) with H_x .

This model is in qualitative agreement with the experimental results: *i*) it explains why in the presence of DMI magnetic nucleation is observed only at one sample edge, *ii*) it explains qualitatively the decrease of nucleation field as the x field amplitude is increased. However, the calculated values of the nucleation field are about one order of magnitude larger than the experimental ones.

FIG. 4. (color online). Nucleation field *vs* H_x for a domain at the edge and in the film calculated using the rigid droplet model (full and dotted line) and the relaxed model (dots and square symbols). Insets: calculated droplet shapes for $H_x/H_{K0} = 0$ (lines) and 0.21 (dots).

Finite temperature model. In a macroscopic sample, magnetization reversal occurs *via* the creation of reversed domains followed by the propagation of domain walls. This is described by the so-called "droplet model" [24, 25] well-known for first order phase transitions. Let us first consider the creation of a cylindrical domain of radius R inside the film. The free energy of this droplet is:

$$E/t = 2\pi R\sigma_0 - 2\mu_0 M_s H_z \pi R^2, \quad (2)$$

where t is the film thickness, $\sigma_0 = \sigma_{00}(1 - D/D_{c0})$ the domain wall energy density in the presence of DMI [8], and H_z the applied magnetic field. The critical droplet radius is $R_c = \sigma_0/(2\mu_0 M_s H_z)$. Below R_c the droplet collapses, whereas above R_c the domain increases its size by DW propagation. This gives rise to an energy barrier for the nucleation of the droplet:

$$E_B = \frac{\pi\sigma_0^2 t}{2\mu_0 M_s H_z}. \quad (3)$$

In an Arrhenius model with attempt time τ_0 , the nucleation field for a waiting time $\tau = \tau_0 e^p$ reads then:

$$H_{n,film} = \frac{\pi\sigma_0^2 t}{2\mu_0 M_s p k_B T} \quad (4)$$

Under the assumption that the magnetic droplet structure is completely rigid (*i.e.* no magnetization rotation in the domains nor in the domain wall, no droplet shape optimization), the application of an in-plane field H_x does not modify the energy of the droplet: the Zeeman energy gained within the half-droplet having a DW magnetization component parallel to H_x is compensated by the loss of energy within the half-droplet with opposite magnetization. This agrees with the results of Fig. 2 which show that the nucleation field for the reversed domain away from the edges does not vary with H_x .

On the other hand, the energy of a half-droplet nucleating at one edge of the sample is modified by the in-plane field. By again assuming a rigid droplet structure, its energy reads:

$$E/t = \pi R(\sigma_0 \mp 2\Delta\mu_0 M_s H_x) - \mu_0 M_s H_z \pi R^2 \quad (5)$$

where the Zeeman energy associated to the in-plane field H_x within the DW volume has been included in the DW energy. The \mp sign refers to the gain/loss of Zeeman energy for a domain wall having its magnetization parallel/anti-parallel to the applied in-plane field, respectively, *i.e.* to the two sample edges. In analogy with the nucleation within the film, the nucleation field at the edges is then:

$$H_{n,edge} = \frac{\pi(\sigma_0 \mp 2\Delta\mu_0 M_s H_x)^2 t}{4\mu_0 M_s p k_B T} \quad (6)$$

This shows that the presence of DMI gives rise to different nucleation fields for DW having magnetization parallel or anti-parallel to H_x . In a sample with DMI, the DDW created at the two edges starting from saturation have opposite magnetization: this explains the nucleation of reversed domains only at one side of the sample and the symmetry of the effect when in-plane field direction and magnetization saturation are reversed. Note that experimentally, nucleation at the hard side of the sample is never observed at larger H_z fields, as the magnetization is always reversed by propagation of the domain walls formed at the easy side for smaller nucleation fields.

Figure 4 (lines) shows the variation of the nucleation field as a function of H_x , calculated for a droplet within the film and a half-droplet having its magnetization parallel to the applied field. The used magnetic parameters for Pt/Co/AlO_x are $A = 16$ pJ/m, $M_s = 1.1$ MA/m, $\mu_0 H_{K0} = 700$ mT, and $D = 2.2$ mJ/m² ($D/D_{c0} = 0.7$).

It can be seen that the droplet model including the presence of large DMI provides an excellent understanding of the measurements: not only the different variation of $H_{z,n}$ vs. H_x within the film and at the easy edge is accounted for, but also the order of magnitude of the reversal fields at the edge is in quantitative agreement with the experiments. In the film, in order to account for the local reduction of the anisotropy field at the defect and therefore reproduce the experimental values of the nucle-

ation field, the energy of the domain wall was reduced by a factor $\epsilon \approx 0.4$ as done previously [26].

Lifting the first two restrictions of the rigid model can be performed semi-analytically, using the ‘small circle’ model (the wall magnetization distribution is assumed to belong to a plane, that cuts the order parameter sphere along a small circle). This provides accurate DW energies, as was shown long ago [27] and checked again here. Once the orientation-dependent DW energy is known, the optimal droplet shape is obtained using the Wulff construction [28]. In the case of the half droplet, in full analogy with the calculation of the contact angle of a liquid droplet on a surface, the difference of edge energies for up and down domain magnetization (that can be analytically calculated with the same model as used in the Zero temperature section) was introduced in the Wulff construction. For each value of H_x , the droplet shapes were first computed (see insets in Fig. 4). Inside the film, an asymmetric elongation along the in-plane field is seen. At the edge, a significant elongation perpendicular to the field takes place, as the DW oriented perpendicular to the field has a much reduced energy and can expand its length. With the shape fixed, the determination of the critical droplet size was then performed [20]. The numerical results of this semi-analytical model, shown in Fig. 4 (symbols) for the case $D/D_{c0} = 0.7$, are very close to experiments. The new feature is the decrease of the nucleation field at the defect in the film, as the in-plane field increases. Comparing calculations and experimental data showed that, within this model, $D \geq 0.7D_{c0}$ is required to get similar evolutions with in-plane field magnitude [20].

The decrease to zero of the nucleation field, seen both experimentally and in the model, is due to the decrease to zero of the DDW energy under a sufficiently large in-plane field. In the case of an in-plane field normal to the DDW, the DW profile can be analytically calculated for an arbitrary value of the in-plane field. For DMI-induced DW moment in the same direction as the field, the DW energy reads (with $h = H_x/H_{K0}$ [29]):

$$\sigma = \sigma_{00}[\sqrt{1-h^2} - (h + \frac{2}{\pi} \frac{D}{D_{c0}}) \arccos h]. \quad (7)$$

This falls to zero at $h \approx 1 - D/D_{c0}$. For other in-plane angles between field and DW normal, the zero crossing takes place at larger fields, reaching H_{K0} when the field is along the DW. This appears to be a unique feature of the Dzyaloshinskii DW.

In conclusion, the nucleation of reversed domains in Pt/Co/AlO_x microstructures was observed to be chiral, and could be explained by the presence of a strong DM interaction within this non-centrosymmetric structure. The in-plane field favours nucleation, at one edge, of DDW having their m_x component parallel to the field. Note that edge nucleation of reversed domains bypasses the topological problem of nucleating skyrmions inside a

sample [30, 31]. Asymmetric nucleation measurements constitute a straightforward way to determine the sign of D and therefore the chirality of Néel walls. A droplet model including DMI gives quantitative agreement with the measurements, even when assuming a complete rigidity of the magnetic structures. A full treatment of the domain wall profile shows that for large DMI and in-plane field the DDW energy becomes negative, a feature hitherto unnoticed. Although all consequences of this specific feature of the Dzyaloshinskii domain walls need to be explored, we already observed nucleation of reversed domains under the application of the sole H_x field.

Supplemental Materials

EXPERIMENTAL SETUP AND PROCEDURE

Measurements were carried out using a wide-field Magneto-Optical Kerr Effect microscope in polar geometry using a 630 nm LED. Figure 5(a) shows the variation of the nucleation field $H_{z,n}$ at the edge of the sample, measured for two values of the applied H_z pulse length, 20 ms and 500 ms. For a fixed H_x field, we have (arbitrarily) defined as the *nucleation field* the H_z field for which 10-15 domains nucleate systematically at the edge. The experimental procedure was the following: with the H_x field switched on, a H_z pulse of fixed length was applied. The H_x field was then switched off, and an H_z field pulse was applied to allow the created domain to enlarge, via domain wall propagation, to a size larger than the spatial resolution of the Kerr microscope. In order to account for the unavoidable misalignment of the H_x electromagnet that can introduce a weak H_z component adding to the H_z pulse, the procedure was carried out twice, starting from positive and negative magnetic saturation, and the presented values are the average of the two measurements.

Note that a larger error bar is associated to $H_{z,n}$ corresponding to the smallest H_x values. This is due to the fact that when the nucleation field for domains within the film becomes smaller than that at the edges, the observation of domain nucleation at the edge is hindered by the expansion of the domains within the film. The criterion which we have used to define $H_{z,n}$ is more difficult to obtain, making the estimation of this field subject to larger errors. It should be noted that several samples with the same magnetic properties have been measured using the same experimental procedure. The minimum field for which the $H_{z,n}$ field is obtained depends on the number and position of the defects within the film.

We have shown in the manuscript that the nucleation field depends on the length of the H_z pulse through the coefficient $1/p$ where $p = \ln(\tau/\tau_0)$. For the two H_z pulses of 20 ms and 500 ms, p is respectively 16.8 and 20 when assuming $\tau_0 = 1$ ns, as usually found in the literature. Figure 5(b) shows the $H_{z,n}$ values multiplied by the respective p values. The invariance of the results with respect to p , within the experimental error bars, is in agreement with the theoretical model.

ZERO TEMPERATURE MODEL

We consider a semi-infinite 1D model to describe the magnetization profile in the vicinity of an edge of the sample. Let x be the coordinate normal to the edge, and z the easy magnetization axis. As the field is applied in the (x, z) plane, and as DMI forces a magnetization

FIG. 5. (a) nucleation fields $H_{z,n}$ measured as a function of H_x for two values of the applied H_z pulse length, 20 ms and 500 ms. (b) the data in (a) have been multiplied by p , respectively 16.8 and 20.

rotation in this plane too, the single unknown is the angle $\theta(x)$ of the magnetization with the easy axis. The energy density reads then

$$E = A \left(\frac{d\theta}{dx} \right)^2 - D \frac{d\theta}{dx} + K_0 \sin^2 \theta - \mu_0 M_s (H_x \sin \theta + H_z \cos \theta) \quad (8)$$

where $K_0 = K_u - \mu_0 M_s^2/2$ is the effective anisotropy constant including the shape anisotropy. Writing down the Lagrange-Euler equations for the minimization of the total energy and integrating back gives the following first integral

$$A \left(\frac{d\theta}{dx} \right)^2 = K_0 \sin^2 \theta - \mu_0 M_s (H_x \sin \theta + H_z \cos \theta) + C^{st} \quad (9)$$

Infinitely inside the sample, the angle is constant (θ_0 in the following) so that the energy reduces to a macrospin one:

$$K_0 e(\theta) = K_0 \sin^2 \theta - \mu_0 M_s (H_x \sin \theta + H_z \cos \theta) \quad (10)$$

The angle θ_0 minimizes this energy, which is solved by

the standard Stoner-Wohlfarth problem under a general field [1, 2].

Thus, Eq. (9) can be re-expressed as

$$A \left(\frac{d\theta}{dx} \right)^2 = K_0 [e(\theta) - e(\theta_0)] \quad (11)$$

the right-hand side being indeed positive as θ_0 minimizes $e(\theta)$.

At the edge of the sample, the micromagnetic boundary condition with DMI reads [22]

$$2A \frac{d\theta}{dx} = D \quad (12)$$

Let us call θ_1 the magnetization angle at the edge. From Eq. (11) and Eq. (12) we have

$$e(\theta_1) - e(\theta_0) = \frac{D^2}{4AK_0} \equiv \left(\frac{2}{\pi} \frac{D}{D_{c0}} \right)^2 \quad (13)$$

This shows that the problem reduces to a two-macrospin problem. The first macrospin θ_0 is independently solved and an analytical solution can be found [1, 2]. Concerning the second macrospin (edge magnetization), Eq. (13) shows that its energy is larger than the previous one which lets expect a switching at smaller fields than for θ_0 , or in other words, an easier magnetization switching at the edges than inside the film.

Around the metastable solution for θ_0 , two solutions for θ_1 can be found which correspond to the two edges, $\theta_1 - \theta_0$ being of the sign of D on the right edge (see Eq. 12). If the symmetry is broken (H arbitrarily oriented in space), the two solutions will disappear (which corresponds to a nucleation event) at different applied field magnitudes, revealing the chirality of edge nucleation process. Note that the easiest branches are iso-barrier curves of the Stoner-Wohlfarth problem. These have already been investigated, when studying the switching field of single-domain nanoparticles at non-zero temperatures, both experimentally through single particle measurements using the micro SQUID technique [4], and theoretically in the macrospin model [5]. These curves are simply shrunk astroids. The solutions for $D/D_{c0} = 0$ and 0.5 are shown in Fig. 6.

This model neglects dipolar couplings (only the shape anisotropy is taken into account), as generally done for ultrathin films. However, the comparison to full micromagnetic simulations (2D mesh, modified OOMMF code) that include the demagnetizing field exactly, is also shown in Fig. 6. Small differences are seen, especially for small in-plane fields because of the magnetostatic charge that appears at the sample edge reduces the edge magnetization tilt [3].

FIG. 6. (a) Nucleation field H_z versus H_x at the edges of the sample, obtained for $D = 0$ and $D = D_{c0}/2$ from Eq. 13. For $D \neq 0$ two branches are obtained, depending on the considered edge orientation. The dots correspond to the micromagnetic simulation including complete dipolar coupling (it has been checked that, in the local demagnetizing field approximation, simulations are in perfect agreement with the model). (b) Sketch of the calculation using Eq. 13 for two different field magnitudes, and for a DMI energy scale indicated by the distance between the two dotted lines. The solutions for θ_1 are the intersection between the upper dotted line and the full curves (indicated by the arrows). For the lower field magnitude (in black), two solutions for θ_1 are found corresponding to both edges. For the higher one (in red), one solution disappears indicating that one edge magnetization is unstable and that nucleation occurs.

MICROMAGNETIC SIMULATIONS

We consider a magnetic ultrathin film grown on a substrate with a capping layer in a different material so that the inversion symmetry is broken along the vertical axis (z). The magnetization is oriented out-of-plane with a strong perpendicular anisotropy. In addition to the standard micromagnetic energy density which includes the exchange, the magnetocrystalline anisotropy, the Zeeman and the demagnetizing energy, we add the Dzyaloshinskii-Moriya contribution (DM) that reads in a continuous form [6]:

$$E_{DM} = D \left[m_z \frac{\partial m_z}{\partial x} - m_x \frac{\partial m_z}{\partial x} + id.(x \rightarrow y) \right] \quad (14)$$

Micromagnetic simulations are based on the Landau-Lifshitz-Gilbert equation integration:

$$\frac{\partial \mathbf{m}}{\partial t} = -\gamma_0 [\mathbf{m} \times \mathbf{H}_{eff}] + \alpha (\mathbf{m} \times \frac{\partial \mathbf{m}}{\partial t}) \quad (15)$$

3D micromagnetic simulations are performed using the homemade micromagnetic solver Micro3D [7]. The following material parameters have been used: exchange stiffness $A = 1 \times 10^{-11}$ J/m, saturation magnetization $M_s = 1.09 \times 10^6$ A/m, uniaxial magnetocrystalline anisotropy constant $K = 1.25 \times 10^6$ J/m³ (along the out-of-plane direction z), Dzyaloshinskii-Moriya constant $D = 2$ mJ/m², Gilbert damping parameter $\alpha = 0.5$. They differ slightly from those considered in the main

text (mainly by the lower A and higher anisotropy $H_{K0} = 0.92$ T), but correspond to a previous work [8].

The thermal fluctuations were neglected and the size of the sample was $100 \text{ nm} \times 1024 \text{ nm} \times 0.6 \text{ nm}$. Starting from positive out-of-plane remanent state, two types of situation were analyzed: *i*) simultaneous application of an in plane field H_x (parallel to the short edge of the sample) and an easy axis H_z field (perpendicular to the film plane). The Dzyaloshinskii-Moriya constant was first set to $D = 0 \text{ J/m}^2$ and after to $D = 2 \text{ mJ/m}^2$; *ii*) application of one single in-plane H_x field with $D = 2 \text{ mJ/m}^2$.

Figure 7(a-b) summarizes the results of the simulations carried out applying $\mu_0 H_x = +0.1 \text{ T}$ and $\mu_0 H_z = -0.7 \text{ T}$ for $D = 0 \text{ J/m}^2$. Starting from out of plane remanent state at $t = 0 \text{ ps}$, the magnetization reverses by nucleation of a domain in the center of the sample, where the demagnetizing field is the largest. The magnetization reversal follows a symmetric mechanism. Figure 7(a) shows the time evolution of the in-plane m_x component of the magnetization across the short edge of the sample. Snapshots at different moments of time are shown on Fig. 7(b): the color is related to the out-of-plane magnetization and the arrows give the in-plane magnetization vector projection. The magnetization reversal starts in the middle of the sample and propagates to the edges.

Figure 7(c-d) shows that the magnetization reversal changes drastically in the presence of DMI. Before the application of the field, the magnetization at the sides of the sample is tilted towards the center, in opposite directions on either side of the sample. The effect of the x -field is to tilt the magnetization in the direction of the applied field; with a positive H_x , the m_x component of the magnetization will have a maximum value on the left side of the sample. Magnetization reversal is then triggered by nucleation of reversed domains at this edge, where the m_x component of magnetization is initially parallel to the H_x field.

Figure 8 (a) shows the effect of an in-plane field $\mu_0 H_x = +0.4 \text{ T}$ applied at time $t = 0 \text{ ps}$, for the case where $D = 2 \text{ mJ/m}^2$. For this value of the x -field, the magnetization simply tilts in the direction of the applied field. The situation is very different for a larger H_x field of $+0.5 \text{ T}$ (Fig. 8(b)). In this case, a domain wall is created starting from the left edge of the sample, and its position stabilizes around the center of the sample due to demagnetizing effects. The creation of this domain wall in the presence of an in-plane field agrees with the results of the model developed in the main text of this Letter, which shows that in the presence of a large DMI, the domain wall energy becomes negative beyond a threshold in-plane field, therefore favoring its formation. Figure 8(c) gives a 2D representation of the dynamics of the magnetization and its evolution towards equilibrium, showing the initial tilt of the magnetization at one edge of the sample, the formation of the domain wall and its propagation away from the edge.

ESTIMATION OF THE MAGNETIC PARAMETERS OF THE SAMPLE

The various micromagnetic parameters of the sample are not exactly known: some of them are directly obtained from characterizations, but some others are more difficult to measure, so that one has to see whether or not, with reasonable values assumed for them, the experimental results can be reproduced. In the case at hand, the relevant parameters are: spontaneous magnetization M_s , exchange constant A , effective anisotropy K_0 (the sum of the volumic, interfacial and shape anisotropies), thickness averaged interfacial DMI D , and p the number of thermal energy quanta $k_B T$ involved in the Arrhenius process, given by $\tau = \tau_0 e^p$ with τ_0 the attempt time and τ the duration of field application for the domain nucleation. We assume for the calculations that $\tau_0 = 1 \text{ ns}$. The value 0.1 ns is often quoted but, as in the Brown theory the attempt time is linked to the damping constant α , and because from the DW dynamics experiments [9] a value of α about 10 times larger than for bulk cobalt was deduced, we took this larger value. Note also that taking $\tau_0 = 0.1 \text{ ns}$ increases p by 2.3 only, for a typical value of 18 that corresponds to $\tau = 66 \text{ ms}$. Finally, the DW energy reduction at the defect in the center of the film is given by the factor ϵ .

For M_s , we have taken the value 1.1 MA/m . The bulk Co value is 1.4 MA/m . SQUID measurements, with large error bars as the sample thickness is only 3 atomic layers ($t = 0.6 \text{ nm}$), are consistent with a lower value of 1.1 MA/m , in agreement with literature.

The effective anisotropy field $H_{K0} = 2K_0/(\mu_0 M_s)$ was directly measured by extraordinary Hall effect under in-plane field. We found $\mu_0 H_{K0} = 0.7 \text{ T}$.

The exchange constant was assumed to amount to 16 pJ/m . For bulk Co, the literature contains values ranging from 10 to 30 pJ/m . The value used here corresponds to an estimate based on the Curie temperature of the ultrathin films [9]. We will discuss below what changes if a lower value of 9 pJ/m is taken.

With these parameters, the primitive DW energy density (without DMI, and under no applied in-plane field) is $\sigma_{00} = 4 (AK_0)^{1/2} = 9.92 \text{ mJ/m}^2$, thus the critical DMI for destabilization of the uniform state is $D_{c0} = \sigma_{00}/\pi = 3.16 \text{ mJ/m}^2$. The DW width parameter is $\Delta = (A/K_0)^{1/2} = 6.4 \text{ nm}$. From these values, we can evaluate the scaling z field of the problem, given by

$$H_{z00} = \frac{\pi \sigma_{00}^2 t}{2 \mu_0 M_s p k_B T} = \frac{4 \pi t}{p k_B T} A H_{K0} \quad (16)$$

and find $\mu_0 H_{z00} = 1172 \text{ mT}$.

In order to estimate the value of the DMI parameter D , we have systematically varied the D/D_{c0} ratio and computed the nucleation fields in the film and at the edge, keeping $\epsilon = 1$ for the moment so that the film nucleation

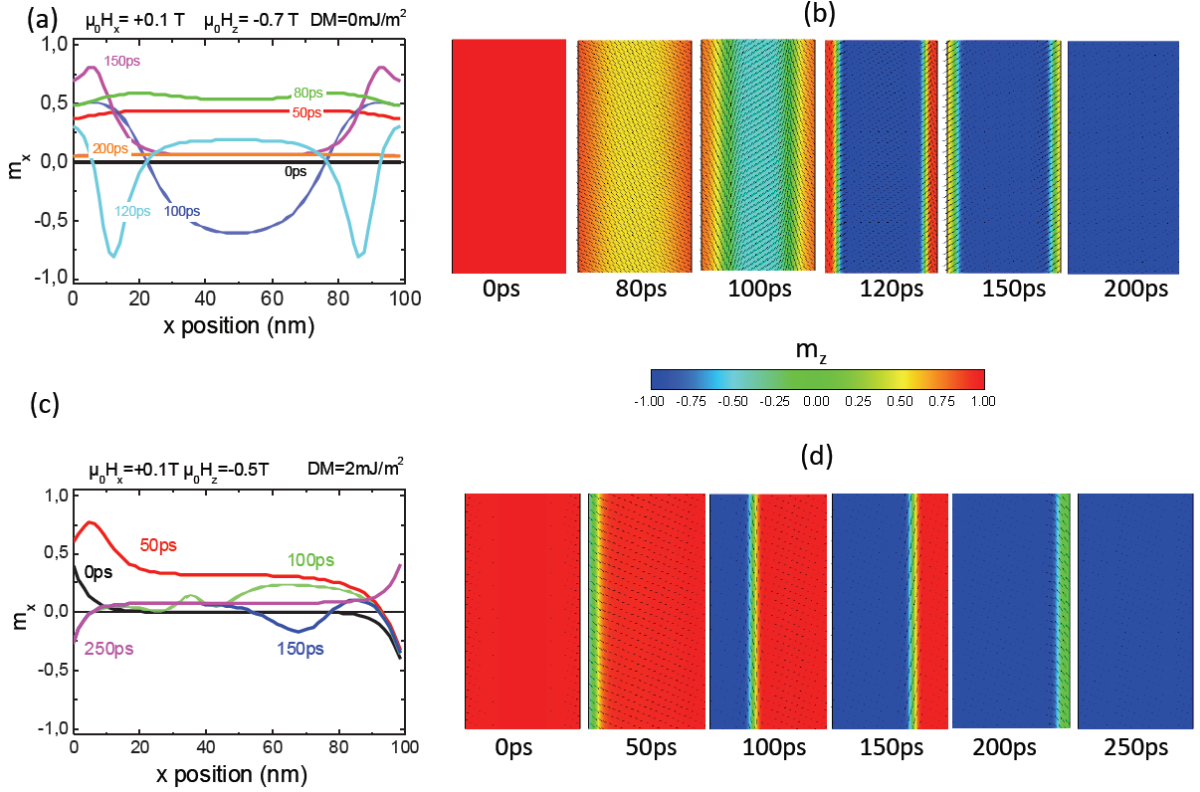

FIG. 7. Micromagnetic simulations showing the modification of the micromagnetic structure of the sample under the effect of: (a) $\mu_0 H_z = -0.7$ T and $\mu_0 H_x = +0.1$ T for $D = 0$ J/m² - the reversal occurs starting from the center of the sample; (b) $\mu_0 H_z = -0.5$ T and $\mu_0 H_x = +0.1$ T for $D = 2$ mJ/m² - the reversal starts from the left edge of the sample.

field is very large. Results are shown in Fig. 9. From both the value of the in-plane field where the edge nucleation field becomes zero (about 250 mT i.e. $H/H_{K0} = 0.36$), and the shape of the curve showing the nucleation field in the film, we find that $D/D_{c0} = 0.7$ fits the best.

Finally, in order to reproduce the experimental value of the nucleation field in the film, we need $\epsilon = 0.42$. From Eq. (16), we see that the value of the nucleation field in the film will be given by the product $A\epsilon^2$. Thus, with a lower value $A = 9$ pJ/m, a value $\epsilon = 0.57$ would be required. This would however shift the value of the in-plane field where the two nucleation fields are equal, from 105 to 56 mT, whereas experimentally it is about 125 mT.

A word of caution is in order here about the physical meaning of this defect parameter ϵ . It was originally introduced in order to model the effect of the defect on the nucleation field [10], in the case of a sole easy axis field, through a reduction of the DW energy. Here, when applying an in-plane field, the DW energy becomes orientation dependent so that the validity of an isotropic reduction of its value by the factor ϵ should be investigated in more detail. We leave this as a subject of future work.
